

The Labor Market Effects of Credit Market Information

Marieke Bos Emily Breza Andres Liberman*

July 2017[†]

Abstract

We exploit a natural experiment to provide one of the first measurements of the causal effect of negative credit information on employment and earnings. We estimate that one additional year of negative credit information reduces employment by 3% and wage earnings by \$1,000. In comparison, the decrease in credit is only one-fourth as large. Negative credit information also causes an increase in self-employment and a decrease in mobility. Further evidence suggests this cost of default is borne inefficiently by the relatively more creditworthy individuals among previous defaulters.

Keywords: household finance, costs of default, credit information

1 Introduction

Credit registries are an important tool used by lenders worldwide to obtain better information about their borrowers and to strengthen repayment incentives. Several studies have documented that credit information affects borrowers' access to credit.¹ However, much less is known about the effects of credit information on non-credit outcomes such as employment that are critical for welfare and policy analysis. Credit information may affect employment indirectly through its effects on credit supply, but more direct channels are also possible. Indeed, while credit registries were largely established to improve the efficiency of credit markets, over time, non-credit actors have increasingly sought out their information (e.g., insurance companies, utilities, landlords, and mobile phone providers). There is ample anecdotal (and some survey) evidence that many employers around the world also query credit registries when making hiring decisions.²

In this paper we provide one of the first measurements of the causal effect of negative credit information on employment and earnings. To do this, we obtain detailed tax, employment, and demographic records merged with data from the Swedish credit registry for a sample of individuals drawn from the universe of pawn-loan borrowers in Sweden. This sample is well suited to measure the employment effects of credit information because it is formed by individuals who are exposed both to financial distress and to frequent spells of unemployment. As a result, individuals in our sample are more weakly attached to the labor market and are likely to bear any employment cost of negative credit information, should this cost exist.

In Sweden, as in most countries (e.g. Miller (2000)), information on the past repayment of debts and other obligations is collected and disseminated through credit registries, and mostly used by lenders to evaluate new borrowers. A borrower who

¹For example, see Musto (2004), Brown and Zehnder (2007), Djankov et al. (2007), De Janvry et al. (2010), Bos and Nakamura (2014), González-Urbe and Osorio (2014), Liberman (2016), Dobbie et al. (2016).

²In the U.S. 47% of the firms check the credit information of their prospective employees according to: <http://www.shrm.org/research/surveyfindings/articles/pages/creditbackgroundchecks.aspx>. In Sweden, where we conduct our empirical analysis, the leading credit registry estimates that roughly 15% percent of all the inquiries it receives are made by nonfinancial institutions conducting background checks of potential employees. These non-financial institutions employ approximately 37% percent of the Swedish labor force. In its website, the Swedish Government Employment Agency lists jobs that currently require a clean credit record: financial, transportation, real estate, retail, and security (See <http://www.arbetsformedlingen.se>).

defaults in Sweden receives an arrear in her file, and a nonpayment flag appears prominently on the top of the credit report.³ Swedish law mandates that each arrear must be deleted from an individual’s credit record three years after it was registered. In turn, the nonpayment flag at the top of the report remains until all arrears have expired.

Our objective is to measure the causal effect on employment of having a past arrear reported in the credit record. However, a simple comparison of individuals with and without reported past arrears is likely to provide biased estimates of the causal effect of interest, as individuals with past arrears are more likely to be unemployed, independent of the nature of their credit information. To identify the causal effect, we exploit a policy change that varied the amount of time that arrears were reported by the credit registry in Sweden. Before October 2003, arrears were deleted on the last calendar day (i.e., December 31) of the third year after first being recorded. Beginning in October 2003, the law was reinterpreted and arrears were deleted exactly three years to the day after they were registered. We refer to the 2001 cohort of defaulters in our sample as the New regime group and the 2000 cohort of defaulters as the Old regime group, and note that the policy change caused a decrease in the average retention time of past defaults for members of the New regime group relative to the Old regime group. Importantly, given that the policy change was announced in March 2003, all individuals who defaulted in 2000 or 2001 did so under the same beliefs about the retention time of their flags of past defaults. Importantly for identification, the key impetus for this change was technological and coincided with an upgrade of the computer systems used by the registry. We note that this policy change was first exploited by [Bos and Nakamura \(2014\)](#).

We use the variation in the retention of past arrears induced by the policy change to identify the causal effect of negative credit information on employment outcomes. However, a simple comparison of individuals in the New and Old regime groups before and after the removal of their respective nonpayment flags would confound any causal effect of credit information with other annual trends in the Swedish economy. Instead, we take advantage of the fact that the policy change modified the retention time of

³Arrears, in turn, are inputs into the credit score. However, non-financial actors typically receive only a strict subset of the information housed in the credit registry and are not able to observe the credit score. In the US, employers are not allowed to observe the FICO score or any other aggregated score. In Sweden, employers cannot see the summary credit score or other key details about the nature of the past delinquencies, but importantly, they do observe the non-payment flag.

the indicator of past defaults differentially for individuals who defaulted in different calendar months across the year. In particular, among individuals who received an arrear early in the year, those in the Old regime had a longer retention time than those in the New regime. In contrast, New and Old regime individuals with an arrear late in the year faced the same retention time. Thus, in our main empirical strategy we compare the yearly employment outcomes of individuals in the New and Old regimes who received a nonpayment flag early in the year with those who received one late in the year and track how these outcomes change after the nonpayment flag is deleted.

We find that the deletion of past defaults has large effects on employment. An individual in the New regime group who defaulted early in the calendar year is approximately three percentage points more likely to be employed the year in which her nonpayment information is removed from the credit registry, relative to an individual in the Old regime and relative to an individual who defaulted late in the year. This difference persists (at least) one year after the information is deleted, albeit with a smaller magnitude. Individuals whose information is removed earlier also earn higher wages and incomes, are less likely to pursue additional years of education, and are more likely to change residence. Moreover, individuals more exposed to the policy are less likely to be self-employed, suggesting that for our population of alternative borrowers, entrepreneurship acts more as a response to involuntary unemployment and less as a high-growth business opportunity. We estimate that removing an individual’s past nonpayment flag one year earlier raises yearly wages by approximately \$1,000, an effect that is four times larger than the increase in consumer credit.

Credit information may affect employment through two channels. First, as discussed above, employers may use credit information directly to screen employees.⁴ Second, improved credit information increases an individual’s access to credit, which may in turn impact employment in many ways. For example, more credit may allow individuals to make investments necessary for finding a job or keeping that job.⁵ Increased credit may also allow individuals to invest in entrepreneurship, thus reducing the relative value of wage labor.⁶ Further, if individuals use labor hours to smooth

⁴Screening by landlords may also contribute to the causal effect of information on employment by affecting mobility. We perform a bounding exercise and show that increased mobility following the removal of credit information can explain at most a quarter of the magnitude of our results.

⁵See, e.g., Karlan and Zinman (2009), Mullainathan and Shafir (2013), and Kehoe et al. (2014).

⁶See Chatterji and Seamans (2012), Hombert et al. (2014), Greenstone et al. (2014), Schmalz et al. (2015), and Adelino et al. (2015).

negative shocks in a precautionary manner, they may reduce their labor supply following an increase in access to credit.⁷ Distinguishing between these two mechanisms is important insofar as the policy responses that emerge from each are very different.

Our baseline results rule out effects predominantly arising from the entrepreneurship and labor smoothing channels, by which more access to credit would lead to more wage employment.⁸ We exploit rich household-level data to provide two additional tests that suggest that employer screening is the main driver of our results. First, we study intra-household effects of nonpayment flag removal. If credit constraints impede a household’s labor supply, then we should expect employment effects on both the individual whose information is deleted as well as the spouse. However, we find no detectable treatment effect on the income of the spouse. Second, we explore differences in the information available to financial institutions versus employers. Crucially, employers are only able to observe a strict subset of the lender’s information. In particular, lenders can observe the number of arrears, while employers can only observe the presence of at least one arrear. We find that access to credit increases upon removal of the nonpayment flag but only for individuals who have many (above median) arrears removed from their record together with the nonpayment flag. There is no increase in credit upon removal of the nonpayment flag for individuals with few arrears. In contrast, we find that the effect of the removal of the past default flag on employment is positive, similar in magnitude, and statistically indistinguishable for individuals with many or few arrears.⁹ With the caveat that the sources of heterogeneity are not randomly determined and could thus reflect unobserved differences in labor market opportunities across groups, we view these results as broadly inconsistent with a model in which employment is mainly determined by differences in access to credit.

This latter result also suggests a potential inefficiency in the use of credit market information by employers. Indeed, one possible interpretation of this result is that banks use all of the available information in their underwriting policies and recognize

⁷See Low (2005), Pijoan-Mas (2006), Jayachandran (2006), and Blundell et al. (2016).

⁸Our results on the extensive margin of employment are also inconsistent with Herkenhoff (2013) and Cohen-Cole et al. (2016a), who study a matching model of the labor market, where access to credit leads to higher unemployment through an increase in the employee’s outside option. Their model also suggests that wages are higher conditional on employment, a test we do not pursue given the fact that conditioning on employment most likely leads to a selection bias in our setting.

⁹We also find that our main effects are stronger among those with fewer years of schooling, consistent with a model in which employers choose to weigh multiple signals of productivity differentially.

that borrowers with few arrears are more creditworthy. However, employers are forced to pool individuals with few or many arrears, leading to a uniform increase in employment post-deletion. Unless the information contained in past repayment behavior that is relevant for banks is not relevant for employment, such pooling disadvantages individuals with fewer initial arrears and also likely disadvantages firms.¹⁰

In summary, our contribution is threefold. First, we document and measure a large employment cost of default associated with credit information among individuals at the margins of formality. Second, our results suggest that this employment cost of default is largely driven by employer screening. Third, we show suggestive evidence that this employment cost of default is inefficiently borne by relatively more creditworthy individuals.

Our paper contributes to a recent academic literature that provides mixed evidence of the employment effect of credit information. [Cohen-Cole et al. \(2016b\)](#) document an increased flow into and out of self-employment after removal of the bankruptcy flag from credit records in the U.S., while [Dobbie et al. \(2016\)](#) estimate that the removal of bankruptcy flags has no effect on employment. There are two key reasons why our results could differ from [Dobbie et al. \(2016\)](#). First, we focus on different types of credit information. While past defaults, which are our focus, can only be observed through credit reports, bankruptcies remain in the public record and can potentially be accessed by employers or job search agencies even when they have been deleted from credit records. Second, the timing of the credit information differs between the two papers. Past defaults in our setting are at most three years old, while bankruptcy flags are removed seven or ten years after filing. One interpretation of these different results is that the informational content of a bankruptcy flag received 7-10 years ago is relatively less important for employers than an individual's more recent delinquencies. Finally, [Balance et al. \(2016\)](#), [Bartik and Nelson \(2016\)](#), and [Cortes et al. \(2016\)](#) study equilibrium effects in the labor markets of bans imposed by U.S. states on the use of credit information on hiring decisions.

Our work also speaks to several strands of household finance research. First, we contribute to the literature on the impacts of credit market information on credit market outcomes.¹¹ Second, we add to previous work that studies the effects of debt

¹⁰The fact that banks and non-financial institutions, like employers, have access to different sets of information is a prevalent feature of credit registries around the world, an asymmetry that arises to provide banks with incentives to report ([Pagano and Jappelli \(1993\)](#)).

¹¹Aside from the empirical evidence cited above, theoretical contributions to this literature include

renegotiation on households.¹² Third, our paper is relevant for the literature on the interaction between entrepreneurship and credit supply (e.g., see cites in footnote six). Our findings also speak to the current academic and policy debates surrounding the appropriate scope of use for credit information by employers, in particular in the context of the increasing use of large data sets in economic decisions, i.e. “big data” (e.g., see Einav and Levin (2013)).¹³

The remainder of the paper is organized as follows. Section 2 describes the data, setting, and empirical strategy. In Section 3 we present the results. In Section 4 we show additional tests that suggest that employer screening is likely to explain part of our results. Section 5 concludes.

2 Measuring the employment cost of default

2.1 Setting and policy change

Swedish credit registries and policy change

Credit registries are repositories of information on the past repayment of debts and other claims, such as utility bills, credit cards, and mortgage payments. In Sweden, credit registries collect registered data from three main sources: the national enforcement agency (Kronofogden), the tax authorities, and the Swedish banking sector.¹⁴ Each reported default triggers an arrear on the borrower’s credit report. In Sweden, any person or company can in principle buy and view the credit records of any other individual.¹⁵ Financial institutions that report to the registry are able to view the entire credit file, including the summary credit score and number of arrears, while non-contributing institutions and private individuals are only shown a strict subset of

Pagano and Jappelli (1993), Padilla and Pagano (2000), and Elul and Gottardi (2015), among others.

¹²See, for example, Dobbie and Song (2015) and Liberman (2016).

¹³For the policy debate, see e.g. the quote in the epigraph and Senator Elizabeth Warren and Representative Steve Cohen’s op-ed in <http://blog.credit.com/2015/09/sen-warren-rep-cohen-its-time-to-stop-employer-credit-checks-125468/>.

¹⁴Swedish banks typically report a borrower to be in default when 90 days past due. Other entities, such as phone companies, exercise discretion when a consumer is reported as delinquent. Individuals have the option of filing an appeal to the courts to correct potential errors.

¹⁵In particular, the law states that credit records are available to other parties as long as the explicit intent is to enter into a contractual relationship. Furthermore, a copy of their credit record and the identity of the requesting party is sent automatically to the individual whose information is requested.

the recorded information. Non-contributing entities observe neither the credit score nor the number of arrears. They instead see a non-payment flag, which indicates at least one arrear.

Before October 2003, Swedish law mandated that all arrears be removed from each individual’s credit report three years after the nonpayment occurred. In practice, the credit registries removed all arrears on December 31 of the third year after the nonpayment occurred. Beginning in October 2003, the Swedish government changed the interpretation of the law to remove every past arrear from the credit registries *exactly* three years after the nonpayment was recorded.¹⁶ Notably for identification, the change was motivated by an upgrade to the registries’ IT capabilities and not by changes to the type or frequency of defaulters.

As shown in Figure 1, the adjustment to the law induced a sharp change in the time series pattern of arrear removals by the credit registries. The figure plots the bimonthly number of individuals whose arrears were no longer reported in the credit registry. The figure shows that before 2003, arrears were almost only removed from the credit registry on the last day of the year.¹⁷ Further, the figure shows a noticeable spike in the frequency of removals in October 2003. This spike corresponds to the removal of the stock of arrears that had occurred between January and the end of September 2000 and that had not yet been deleted from the credit registry. After October 2003, the frequency is more smoothly distributed over the year, in effect following the distribution of nonpayments across the year, three years earlier.

Identification intuition

We attempt to identify the causal effects of past nonpayment information on employment and other labor market outcomes. A simple correlation between credit information and employment would likely be plagued by both reverse causality and omitted variable bias.¹⁸ Rather, an idealized experiment to identify this causal ef-

¹⁶The Swedish government announced their decision to change Paragraph 8 of the law that regulates the handling of credit information (KreditUpplysningLagen or credit inquiry law) on July 2003, and the law change took effect in October 2003. See <http://rkrattssdb.gov.se/SFSdoc/03/030504.PDF>

¹⁷In our bimonthly data, an individual who received an arrear on December 1 but had that arrear removed on December 31, is first observed without an arrear in February, three years later.

¹⁸For example, individuals who lose their jobs and remain unemployed may have a higher propensity to default on their debts (Foote et al. (2008) and Gerardi et al. (2013)). Further, loan repayment and job performance may both be affected by traits such as responsibility and trust-worthiness.

fect would consider two identical groups of individuals who defaulted in the past and subsequently repaid but, as a result, have a bad credit record. In that experiment, the credit registry would delete the information for one group earlier than scheduled and any difference in the employment of both groups could be causally assigned to the removal of information.

In our empirical setting, we use the variation in the retention time of publicly observable arrears induced by the 2003 policy change in Sweden to approximate this idealized setting. One naive empirical strategy would be to focus on nonpayment cohorts before the policy change and to compare individuals who defaulted earlier in the year to those who defaulted later in the year. After all, the early defaulters did experience longer retention times than the end-of-year defaulters. However, it is likely that individuals who default at different times during the year differ in ways that may have systematically different labor market outcomes.¹⁹ Further, individuals may have been aware of the pattern of deletions and chose to time their defaults accordingly if possible. Hence, a comparison of the employment prospects of individuals who defaulted early and late in the same year before the policy change is likely to be biased.

An alternative identification strategy is to compare individuals who defaulted in 2000, which we define as the “Old regime” group, with those who defaulted in 2001, which we define as the “New regime” group, observing that the average retention time is lower for the New regime group. Indeed, the policy change induced unexpected variation in the length of time that information was retained in the credit registries. Hence, individuals who defaulted in 2000, three years prior to the policy change, did so under the same beliefs about retention time as individuals who defaulted in 2001, two years before the policy change. The unexpected nature of the policy change allows us to rule out any strategic behavior of individuals timing their default so as to experience shorter retention times. However, this strategy is also problematic as there may be other differences between individuals who defaulted in 2000 and 2001 that are correlated with labor market outcomes.

Instead, we combine the two empirical strategies—New versus Old regime cohorts

¹⁹Evidence consistent with this fact is presented graphically in the Internet Appendix. We plot the average probability of receiving any wages two years after their last default by the bi-month of default, for individuals in our sample who defaulted in 2000 or 2001. The probability of employment varies between a max of 85% for February-March defaulters to a low of 77% for October-November defaulters.

and early versus late defaulters within the calendar year—for identification. We compare the difference in the employment prospects of individuals in the New regime whose default was reported early and late in the year with the same difference for individuals in the Old regime. We observe that individuals in the New regime group who defaulted at any point in 2001 and individuals in the Old regime group who defaulted late in 2000 were subject to the same three-year retention times. Individuals in the Old regime group who defaulted early in 2000 were subject to more than three years of retention time. For example, individuals in the Old regime group who defaulted in March 1 were subject to three years and seven months of retention time. This double-difference analysis is the basis of our identification strategy. We then compare the employment outcomes for each individual before and after the three-year post-arrear date. The identification assumption we make is that, in the absence of the policy change, the difference in employment outcomes of individuals in the Old and New regime groups whose defaults were reported early and late in the year would have remained constant before and after the deletion of the nonpayment flag. In Section 3.1 we provide pre-trends evidence that is consistent with this assumption.

Finally, note that among individuals in the New regime group, those who defaulted earlier in the year experienced a larger decrease in retention time than those who defaulted later in the year. This suggests an additional test of our identification strategy: the effects of the policy change should be monotonically decreasing in the time of the year during which individuals’ defaults were initially reported. In Section 3 we provide evidence that is consistent with this intuition.

2.2 Data

Our initial sample comprises the near universe of alternative credit borrowers in Sweden. This sample was generously supplied by the Swedish pawnbroker industry and contains registered information about the 332,351 individuals who took out at least one pawn loan between 1999 and 2012 (approximately five percent of the Swedish adult population). It is true that individuals who resort to pawn borrowing are systematically different from the Swedish population at large. Given that individuals typically turn to pawn loans when they are not able to access sufficient credit from formal sources to meet their demand, unsurprisingly, pawn borrowers tend to be poorer, are less likely to be employed, earn lower wages conditional on being employed,

and are less likely to be homeowners (Bos et al. (2012)).²⁰ To paint a more complete picture of the population of Swedish pawn borrowers, we plot for the years of our sample the age, education, income and credit score distribution, and compare it to the distributions of the Swedish population at large (see Internet Appendix). From these plots, we learn that on average, the Swedish pawn borrower is younger, less educated, earns a lower income, and has a worse credit score (a higher probability of default) compared to the average Swede. Importantly, the policy we study only matters for the potential outcomes of individuals with arrears. So, it is useful to ask what fraction of total defaulters in Sweden are represented in our sample. While the average Swede has a 10% likelihood of having at least one arrear, the number is 46% in our sample. This implies that we have data on approximately one quarter of arrear-holders in the country. Given the poor financial records and weak attachment to the labor market of alternative borrowers, it is exactly this population that may experience the greatest benefits from a clean credit record.

We obtain a bimonthly panel of credit data from the leading Swedish credit registry, Upplysningscentralen that ranges from 2000 to 2005. Each bimonthly observation contains a snapshot of the individual’s full credit report (i.e., amount of credit and repayment status on different obligations). Swedish credit registries also have access to data from the Swedish Tax authority and other agencies. This enables us to further observe variables such as home ownership, age, marital status, yearly income from work, and self-employment. Importantly, we observe when an individual’s nonpayment was first reported and subsequently removed by the credit registry.

To measure labor market outcomes, we match the credit registry data with information obtained from Statistics Sweden (SCB). These data are at the yearly level from 2000 to 2005 and include information on each individual’s employment status. The data also include measures of individual income, wages, and income from self-employment as well as total household disposable income. We defer an analysis of summary statistics of our main outcome variables until after we have presented our sample selection criteria.

²⁰See Bos et al. (2012) for an extensive discussion of the household characteristics of pawn borrowers in Sweden compared to the full Swedish population and for a comparison of pawn borrowers in the Swedish and US.

2.3 Implementation of empirical strategy

The key empirical goal of the paper is to understand what happens when the defaulter flag is removed exogenously from the top of the credit report. The natural experiment in the paper allows us a unique opportunity to use quasi-exogenous variation to measure this impact. However, as in any heterogeneous treatment effects setting, the experiment doesn't impact all households equally. For example, households with no arrears (the always-takers) and households who continue receiving arrears even after the policy announcement (the never takers) should not be affected directly. Thus, we make a series of sample restrictions to attempt to isolate the individuals who, *ex ante*, are most likely to be affected by the policy (the compliers).

First, we include in our analysis sample only individuals who received an arrear for nonpayment in 2000 or 2001 and thus had those nonpayment flags removed in 2003 or 2004. Second, we further restrict the sample to those individuals who did not receive additional arrears in the subsequent 20 months (i.e., who repaid all their delinquencies) before the policy change. This restriction reduces the sample size by 67% (i.e., 33% of all individuals our sample who had an arrear in 2000 or 2001 did not re-default in the next 20 months). The rationale for this 20-month window is as follows. Recall that our identification strategy requires categorizing individuals into the New and Old cohorts. With a shorter than 20 month window, it becomes unclear whether an individual who recorded an arrear in March 2000 and another in October 2001 should be in the Old or New group. It is also essential that our sample construction be predetermined relative to the policy change. Thus, a longer than 20 month window would be contaminated by the endogenous choice of re-default caused by the policy change.²¹

Third, because of the bimonthly nature of the credit registry data shared with the researchers (e.g., December-January defaulters are first reported in the February snapshot, February-March in the April snapshot, and so on), we restrict our sample to defaults occurring strictly after January 2000.²² For a similar reason we omit individuals whose defaults are removed from the credit registry in the December-January 2001 bimonth. Finally, we focus on individuals who are between 18 and 75

²¹Note that some individuals in our sample obtained a new arrear after this 20 month period. Thus, they maintain a nonpayment flag in their records after the original arrear received in 2000 or 2001 is removed, which reduces the power of our tests.

²²Note that the credit registry updates its information and makes it publicly available on a daily basis. The research team, however, was only allowed access to bimonthly snapshots of the data.

years old the year before information on past defaults is removed from the credit registry. These selection criteria, which are necessary to implement our empirical strategy, result in a sample of 15,232 individuals.

Figure 2 depicts the time line of the policy change and how it affected the length of time in which nonpayments were reported for the individuals in our sample. In particular, Old regime group individuals whose nonpayments were recorded in the first months of the year were reported in the credit registries for a maximum of almost three years and eight months until the end of September 2003, while New regime group individuals whose nonpayments were recorded in the first months of the year were reported in the credit registries for exactly three years. Figure 2 also shows the number of past defaulters in each of the bimonthly bins. We note that while there are substantially more early defaulters than late defaulters in both cohorts, these patterns are remarkably consistent across New and Old regimes.

Table 1 reports the excess number of months above three years that the nonpayment flag of individuals in each of the four cells—New regime-Early, New regime-Late, Old regime-Early and Old regime-Late—is retained in the credit registry after the policy change. All individuals in the New regime have a retention time of three years (reported in the table as zero excess months above three years). Old regime individuals who defaulted early in the year have on average six extra months of retention time, calculated as follows: February defaulters have on average 7.5 extra months of retention time of their nonpayment flag—from any day in February to the first day of October—, March defaulters have 6.5 extra months, April defaulters have 5.5 extra months, and May defaulters have 4.5 extra months. Assuming a uniform distribution of individuals across all four months results in an average extra retention time of six months. Finally, Old regime individuals who defaulted late in the year have one extra month of retention time (calculated as: August defaulters have 1.5 extra months, September defaulters have 0.5 extra months, and October and November defaulters have exactly three years of retention time given that the policy change occurred precisely on the first day of October).

We define the indicator variable New_i to equal one if borrower i 's last nonpayment occurred during 2001 and zero if it occurred during 2000. We interact New_i with the dummy variable $Early_i$, which distinguishes between individuals whose nonpayments occurred early and late during the year. Because in our data each individual is assigned to a bimonthly cohort of defaulters, $Early_i$ equals one for individuals whose

last nonpayment occurred in the February-March or April-May bimonths, and zero for individuals whose last nonpayment occurred in the August-September or October-November bimonths.²³ Finally, we create a dummy, $Post_{i,t}$, which equals one for all event years after borrower i 's nonpayment signal is removed (2003 for the Old regime and 2004 for the New regime). Note that the variable $Post_{i,t}$ is measured in event time t , which is normalized to zero in 2000 for the Old regime group and in 2001 for the New regime group. Thus, event time year three represents the year in which the nonpayment flag is deleted from the credit registry for any individual in our sample. Our main specification is the following reduced form model:

$$\begin{aligned} Employed_{i,t} = & \omega_i + \omega_t + \omega_\tau + \beta New_i \times Early_i \times Post_{i,t} + \delta Post_{i,t} + \\ & \gamma New_i \times Post_{i,t} + \lambda Early_i \times Post_{i,t} + \varepsilon_{i,t}. \end{aligned} \quad (2.1)$$

We include individual fixed effects ω_i , calendar year fixed effects ω_τ , and event time fixed effects ω_t , as well as all double interactions that are not absorbed by fixed effects.

For completeness, we present in the Internet Appendix selected Swedish macroeconomic indicators throughout our sample period.²⁴ The table suggests that although there is some volatility in economic aggregates, no major recessions were observed in Sweden during this time period. In particular, GDP growth dropped from 4.7% in 2000 to 1.6% in 2001, although unemployment dropped from 5.8% to 5% in the same time frame. Inflation is relatively constant and below 2.41%, and unemployment varied between 5% and 8% throughout the sample period.

Note that ω_i absorbs the baseline and interaction coefficients of New_i and $Early_i$. The coefficient β , our key parameter of interest, measures the differential probability of being employed for the New and Old regime group, for individuals whose nonpayment was reported early in the year relative to those whose nonpayment was reported late in the year, the year(s) after each individual's nonpayment is no longer reported relative to the three prior years. The coefficients δ and λ capture differences in employment for individuals in the Old regime whose nonpayment occurred late and early in the year, respectively, the years after the arrear is deleted. Finally, γ

²³Note that to make the early and late groups comparable in size we exclude the June-July cohort. However, below we include individuals in this cohort when we measure differential effects by differential intensity of the treatment by month of nonpayment.

²⁴All our outcomes are at the yearly level, and any baseline variation in these levels that is driven by macroeconomic shocks is absorbed by the year fixed effects, ω_τ .

captures differential employment trends for all New regime group individuals after their nonpayment information is no longer publicly available.

2.4 Summary statistics

Before presenting the regression results, in Table 2 we present selected summary statistics. We focus our analysis on employment outcomes, broadly construed. In addition to earnings and whether an individual has a job, we also consider alternatives to labor income, including seeking more education and turning to self-employment income. The top panel presents a brief definition for each of our outcome variables, and the lower panel displays selected sample statistics.

Our summary stats are estimated on the three years before nonpayment flags are removed, which correspond to the years 2000, 2001 and 2002 for the Old regime group and 2001, 2002 and 2003 for the New regime group. Our main outcome variables are *Employed*, a dummy that equals one for individuals who were continuously employed throughout the year, and 1 ($Wages > 0$), a dummy that equals one if the individual received any wage income during the year. During those years, an average of 43 percent of individuals in our sample are employed during the full year, while 79 percent received some positive wage income.

We view the discrepancy between both averages as consistent with two particular facts about our sample. First, individuals in our sample have much higher job instability than the average Swede, in part because of their lower levels of education. As a result, an individual in our sample is more likely to receive some positive income from wages and at the same time experience unemployment spells during the year, thus being categorized as not fully employed as per our main outcome variable. Second, because of their lower education, individuals in our sample are more likely to have temporary, low-skill employment contracts. We verify this notion using aggregate data from Statistics Sweden on the relationship between education levels and labor market contracts for the general Swedish population. We see that 14.1% of the employment of individuals who drop out of high school is temporary, while this figure drops to 10% for individuals with more than high school.²⁵

Average after-tax income is equal to SEK91,400 (approximately \$12,000). We

²⁵See http://www.statistikdatabasen.scb.se/pxweb/sv/ssd/START__LE__LE0101__LE0101S/LE01012013S22/?rxid=91289227-eae0-41b9-8da5-d9e7bbcf5e66

use a log transformation of our income measures, which are in units of hundreds of Swedish Kronor (SEK), as the outcome variable in our regression tests, and average $\log(\text{Income}+1)$ is 5.6. Roughly five percent of all individuals in our sample are self-employed. Finally, individuals are 42.8 years old on average and 60 percent male. The low rates of formal employment and average wage earnings confirm that our sample is indeed situated at the margins of formality, where negative credit information could lead to costly labor market exclusion.

For comparability, we present in the Internet Appendix selected summary stats obtained from the credit registry for a random sample of the Swedish population and for a random sample of individuals with at least one arrear, both as of 2003. The average probability of having any wage income in our analysis sample is closer to the sample that represents all Swedish defaulters (79% in our sample versus 86% for the random sample conditional on default). Moreover, based on our calculations, the average income in our sample corresponds roughly to the 10th percentile of the income distribution in Sweden as of 2003, while the average income for the Swedish sample conditional on any arrear is at the 13th percentile that same year.

One limitation of the data is that it does not include information on the individual's job or industry. In order to provide more context to our sample, we obtain from Statistics Sweden information on the most common jobs categorized by education levels during our sample period. For individuals with 9 to 12 years of education, common jobs include; caretaker in the healthcare sector, retail salesperson, finance and sales associate, truck driver, construction worker, and janitor.²⁶ We note that several of these industries, such as financial services, transportation, retail, and construction, report to check credit records for their applicants.²⁷

3 Results

3.1 Graphical evidence

We start by showing graphically the event-time evolution of the average outcomes, which provides evidence in support of our identification assumption. The identifica-

²⁶See http://www.statistikdatabasen.scb.se/pxweb/sv/ssd/START__AM__AM0208__AM0208B/YREG26/?rxid=f45f90b6-7345-4877-ba25-9b43e6c6e299.

²⁷See <http://www.arbetsformedlingen.se>.

tion assumption for regression (2.1) is that, in the absence of the policy change, the probability of being employed for the New and Old regime groups would have evolved in parallel between early and late in the year defaulters. We provide evidence that supports this assumption in Figure 3. The top panel shows the average of *Employed* (we omit subindices for brevity), defined as a dummy for whether the individual was fully employed throughout the entire year, as well as $1(Wages > 0)$, the average of a dummy that equals one for individuals who receive any positive wage during the year. The x-axis shows event time years, which are defined starting at zero in 2000 for the Old regime group and in 2001 for the New regime group. We look for parallel trends in the preperiod, and indeed, there are no detectable differences in the trends of the difference of either variable between early and late defaulters in the New and Old regime groups during the three years before removal of the nonpayment flag (i.e., in event times 0 to 2).²⁸ Similar effects can be observed for the average log income and log wage income where zeros have been replaced by ones, shown in the lower panel. These graphs provide evidence that is consistent with our identification assumption. Below we also provide a formal test of (absence of) pretrends using lagged outcomes in a regression setting.

The figures also hint at our main results: individuals in the New regime group who default early in the year exhibit a higher probability of employment and earn higher incomes after their nonpayment flags are removed relative to similar individuals in the Old regime. In general, the graphs show that the difference in employment outcomes between early and late defaulters is positive but decreasing over time for both cohorts, but, in event time 3, that difference shrinks less for New regime. This suggests that the effect is driven by a relatively lower probability of employment for individuals in the Old regime who default early in the year, which is consistent with the credit information mechanism. For these individuals, the past nonpayment flag remains in the credit records for an extra six months (above three years), relative to half an extra month of retention time for Old regime individuals who defaulted late and no extra months for individuals in the New regime group, as is shown in Table 1.

²⁸In the Internet Appendix we present plots of the average evolution of each outcome without differencing, i.e., Old-Early, Old-Late, New-Early, and New-Late.

3.2 Main results

Table 3 presents the output of regression (2.1). Columns 1, 2, and 3 present the regression results when the outcome is *employed*. Column 1 documents that the probability of employment for an individual whose information is reported for a shorter period increases by 2.8 percentage points the year the nonpayment is removed from the registry (year three). This effect is a 6.5 percent increase relative to the preperiod average employment rate (43 percent).²⁹ Column 2 shows that this effect is also significant for the combined two years after removal, although with a lower magnitude. Column 3 shows that focusing only on the second year after removal, the point estimate continues to be positive, although statistical significance is lost.

Columns 4, 5, and 6 of Table 3 show the same pattern when employment is defined instead as receiving any positive labor market income during the year. Indeed, Column 4 shows that New regime group individuals who defaulted early in the year are 3 percentage points more likely to earn positive labor income, and this effect persists two years post information removal. Furthermore, the probability of receiving positive income from work is positive (and statistically significantly so) and of the same magnitude during the second year (column 6). The persistence of these effects suggests that default induces a longer-term cost in the labor market, which is consistent with the findings in the labor economics literature that a longer unemployment spell has a persistent effect on future unemployment (e.g., Kroft et al. (2013)).³⁰

In the Internet Appendix, we present regression results using our main specification (i.e., regression (2.1)) where the outcome variables are lagged by one year. These regressions measure effects one year *before* the information is removed, and are akin to a test of pre-trends in a standard diff-in-diffs specification. In all cases, the coefficient of interest is not detectably different from zero, formalizing the lack of visible pre-trends in Figure 3 and providing further support to our identification assumption.

We explore the impact of credit market information on additional labor market

²⁹In the Internet Appendix we present a robustness result where we exclude the individual fixed effects. Results are slightly larger in magnitude but essentially unchanged from our main test.

³⁰We cluster standard errors at the individual level to avoid serial autocorrelation due to the panel nature of the data. One potential concern is that standard errors are serially correlated across bimonths of default. In the Internet Appendix, we present estimates of regression (2.1) using standard errors clustered at the bimonth of default by 5-year preperiod age groups (52 clusters). The significance is essentially unchanged relative to the main specification.

outcomes. Columns 1 through 3 of Table 4 display the output of our main regression model (2.1), where the postperiod corresponds to two years after the removal of the nonpayment flag, for an array of additional labor market outcomes including the log of income from work, $\log(wages + 1)$, the probability of being self-employed, and the log of total post-tax income, $\log(Income + 1)$. Income measures are in hundreds of SEK.³¹ In column 1 we find that individuals whose nonpayment flag was retained for less time earn statistically significantly higher wage incomes.

But how large is this earnings effect? In the Internet Appendix we show that running our main regression in wage levels implies an increase in wages of 3,987 SEK, or roughly \$480. Recall from Table 1 that this \$480 treatment effect is the result of a reduction in retention time of only 5.5 months. Thus, this cost annualizes to \$1,047 per year or \$3,142 over the three years in which default is flagged publicly. This effect is economically large, approximately 7% of the average annual earnings for individuals in our sample.³²

Recall that improved credit information may also directly increase the amount of credit financial institutions are willing to supply. To get a sense of the relative magnitudes of the earnings and credit supply effects, in the Internet Appendix, we run our main regression using credit outcomes, specifically, the amount of consumer credit and a dummy for any positive consumer credit. We find that the removal of the nonpayment flag leads to an increase in credit of 903 SEK (column 2), which implies a total annualized effect of \$236 in credit per extra year of retention time. Thus, the effect of credit information on wages is roughly four times the effect on credit, and suggests that, quantitatively, the labor costs of default may be more important than the loss of access to credit, at least among individuals at the margins of formality.

The wage earnings effect combines the extensive margin effect documented above with an intensive margin effect of higher salaries conditional on employment. We estimate in a back-of-the-envelope calculation that approximately 53 percent of the earnings effect is driven by the extensive margin.³³ These calculations imply impor-

³¹In the Internet Appendix we present the results of specifications with alternative transformations of the dependent variable: a) using the hyperbolic sine transformation as an alternative to replacing zeros in the logarithm, and b) using the level of wages.

³²We also find that the impacts on credit are short-lived and only last one year, while the earnings impacts persist across (at least) two years.

³³We obtain this fraction as follows. First, the average wage of individuals who transitioned from zero wages to positive wage income in event time 2, the year before the past default flag is removed, is 71,200 SEK. Thus, a 3% extensive margin effect from Column 4 in Table 3 corresponds to a wage

tant effects on both intensive and extensive margins, which is consistent with the existence of labor market frictions that prevent an adjustment on wages alone.³⁴

In addition to wages, individuals may also earn incomes from self-employment activities. Column 2 of Table 4 shows that shortened retention times lead to a decrease in self-employment activities. This decrease is despite an increase in the availability of credit, which suggests that many individuals in our sample use self-employment as a response to unemployment rather than as a high-growth venture.³⁵ Summing across the increase in wage earnings and the decrease in self-employment income, we find an overall increase in post-tax income in column 3 of Table 4.

As an additional robustness test, in the Internet Appendix, we present the results of running our main regression test on a sample where we shift the definition of New and Old regime groups one year ahead. That is, we define a Placebo New regime group as individuals who defaulted in 2001 and a Placebo Old regime group as individuals who defaulted in 2002, and use *employed*, a dummy for positive wage income, and the log of wages plus one as outcomes. In all three cases, the estimated coefficient of interest is not significantly different from zero at conventional levels and even takes the opposite sign to our main results, which supports the assumption that our main results are not driven by differential secular employment trends of defaulters.

3.3 Results by treatment intensity

Our identification strategy relies on variation in the retention times of nonpayment information induced by the policy change. To further support our identification, we exploit the bimonthly nature of our credit data and study whether individuals who were exposed to *differential* retention times, measured by the time of the year in which they defaulted, experience differential labor market responses.

We categorize individuals in our sample into five groups according to the bimonth in which they defaulted: February-March, April-May, June-July, August-September, and October-November.³⁶ This categorization of default cohorts induces a monotonic

effect of 2,129 SEK. Thus, the extensive margin represents a $\frac{2,129}{3,987} = 53.4\%$ of the total wage effect of 3,987 SEK shown in the Internet Appendix.

³⁴E.g., the typically high level of unionization in Sweden contributes to a limited scope for adjustment along the wage margin. For statistics on the trade union density in Sweden see for example https://stats.oecd.org/Index.aspx?DataSetCode=UN_DEN.

³⁵See Banerjee et al. (2015) for an application of this idea in India.

³⁶In this section, the sample includes individuals who defaulted in the June-July bimonth, which

ordering of exposure to the policy change, defined as the average reduction in the number of months during which the nonpayment flag was available in the credit registry, for New relative to Old regime group individuals: the August-September cohort has a one month average reduction, June-July has a three month average reduction, April-May has a five month average reduction, and February-March has a seven month average reduction. Note that the October-November cohort has, by construction, a zero month reduction in retention time.

We hypothesize that if past arrears affect the probability of being employed, then the measure of months of exposure to the policy, i.e. the number of fewer months in which past arrears are reported, should be positively correlated with the probability of being employed during a given year. To test this hypothesis, we present in Table 5 the results of a regression where we allow the effect of a shorter retention time of past defaults to be linear in the length of exposure, $Exposuremonths_i$, defined as the reduction in the retention time for the New cohort relative to the Old cohort (i.e., by bimonth of default):

$$1(Wages > 0)_{i,t} = \omega_i + \omega_t + \omega_\tau + \beta Exposuremonths_i \times New_i \times Post_{i,t} + \delta \times Post_{i,t} + \gamma New_i \times Post_{i,t} + \sum_{t=1,3,5,7} \lambda_t 1(Exposuremonths_i = t) \times Post_{i,t} + \varepsilon_{i,t}. \quad (3.1)$$

The coefficient of interest is β , which measures the average change in the probability of receiving wage income for each month of exposure. As the table shows, one month of exposure corresponds to approximately a 0.5% increase in the probability of receiving any wage income and about a 0.4% higher log wage income. This evidence are consistent with the hypothesis that past arrears affect the probability of being employed.

As an additional test, in the Internet Appendix we plot the coefficients of a regression where we assign individual dummies to each bimonth of default throughout the year, in effect measuring effects of differential retention time across the bimonth of arrear. Consistent with our identification assumption, the measured effect is stronger for individuals who experienced greater reductions in retention times because of the month in which their default occurred, although standard errors are relatively large. Further, the pattern is monotonic for three, five, and seven months of exposure.

increases the number of individuals and observations relative to previous tests.

3.4 Other Results: Mobility and Education

We explore two additional margins that may be affected by changes in credit market information. First, we measure whether increased retention time affects an individual’s geographic mobility within Sweden.³⁷ Because landlords commonly check a prospective lessee’s credit history before signing a lease agreement, we hypothesize that individuals may be more able to relocate if negative information is held by the credit registry for a shorter period. Moreover, improved access to employment opportunities may also induce mobility. We test this hypothesis in columns 1 and 2 of Table 6 and define the outcome variable $relocates_{i,t}$ as an indicator for whether an individual moved to a different municipality between years $t - 1$ and t . In column 1, we consider the treatment effect for the entire analysis sample and find that individuals who experienced a shorter retention time are 1.1 percentage points more likely to move, relative to a baseline mean of 7.7 percent. Although the coefficient is large in relative terms, it is not statistically significant at standard levels (p-value = 0.19). Given that individuals in our sample have very low home ownership rates (9.6 percent) and that credit checks for residential rental leases are common in Sweden, in column 2, we restrict the sample to the set of individuals who did not own a home in the preperiod. Here we find that individuals who are not home owners are 1.6 percentage points more likely to move across postal codes when their negative credit market information is available to the credit market for less time. While the results are only significant at the 10 percent level, we find them highly suggestive of a type of mobility lock-in the rental market caused by credit market information.³⁸

Improvements in mobility to better labor markets induced by the removal of bad credit information may have a causal role explaining the employment results. To test for this possibility, we perform a bounding exercise and find that this lock-in effect can explain at most 27 percent of the baseline effect of information on employment in Table 3.³⁹ Again, the direction of causality may also flow in the opposite direction

³⁷In unreported results, we study the effect of negative credit information on the propensity of individuals in our sample to relocate out of Sweden. Consistent with past arrears reducing labor market opportunities, we find that individuals are slightly less likely to leave the country following the early deletion of their past defaults, although the effect is small.

³⁸This pattern is similar to the housing lock-in documented by Struyven (2014) in the case of Dutch homeowners with high loan-to-value ratios.

³⁹We estimate this fraction as follows. We repeat the mobility regression result conditioning on individuals who moved who also changed employment status, which implies a coefficient of 0.8%. If we fully attribute this coefficient to the causal effect of increased mobility following the early

– a change in employment status may facilitate relocation. Thus, it is likely that mobility is not the main driver of the effects of credit information on employment and wages.

Second, we ask whether some individuals respond to decreased labor market opportunities by adjusting their demand for additional schooling. When wage jobs become more scarce, the opportunity cost of schooling decreases, which may in turn increase the demand for schooling.⁴⁰ This may be especially true in Sweden, where educational loans do not require credit checks and where the costs of education are relatively low. In column 3 of Table 6, we find evidence that education is indeed one margin of adjustment used by individuals. Decreased retention time decreases the number of years of education by 0.0355. While the effect is small in magnitude, it is significant at the 5 percent level.

Taken together, our results provide a consistent characterization of the effects of credit market information on labor markets. We interpret these results as the inverse of our baseline effects: information on past defaults reduces the probability that an individual is and remains employed. Individuals respond to this decrease in employment opportunities by turning to self-employment activities and seeking additional education. As a result, individuals earn lower wages and lower total incomes two years after the information is removed from the credit registry.

4 Mechanisms and Additional Evidence

4.1 Credit Information or Credit Supply?

We document an economically large employment cost of default among individuals at the fringes of the labor and credit markets. Two possible channels could drive this effect. First, in the Internet Appendix, we show that credit supply increases when negative information is deleted.⁴¹ Thus, it is possible a priori that such an increase in credit supply might facilitate investments in job search or investment in labor productivity, which may lead to more employment. For example, credit may

removal of credit information, then mobility can explain up to $\frac{0.8\%}{3\%} = 27\%$ of the baseline effect on employment (denominator taken from Column 4 in Table 3).

⁴⁰See Charles et al. (2015) for evidence of this idea in the US.

⁴¹In particular, we run our main specification (regression (2.1)) where the outcomes are: 1 (*Consumer* > 0), a dummy for any consumer credit, and *Consumer*, the level of consumer credit. In both cases the coefficient of interest is positive and highly significant.

allow an individual to pay for a car repair, which in turn may improve punctuality at work. Second, employers might use credit information directly to screen workers. While both effects may be at play, we present five pieces of evidence that suggest that employer screening plays a key role above and beyond the role of credit supply in rationalizing our findings.

First, recall that the magnitudes of the labor market earnings effects in Section 3.2 are four times larger than the commensurate increase in credit supply. Thus, for the credit effects to explain the entire earnings result, the labor market returns to capital would need to be on the order of 400%, an implausibly high number. Second, recall from Table 4 that improved credit information (and subsequent access to credit) leads to a reduction, rather than an increase, in self-employment activities. This result implies that a subset of individuals with a bad credit record are unconstrained enough to pay any costs required to be self-employed. It seems unlikely that the costs of entering the labor market would be of a larger magnitude.

Third, we study how the removal of negative credit information affects the affected individual’s spouse’s employment. Intuitively, if households are restricted in their access to credit, then a relaxation of credit constraints would also allow an individual’s spouse to supply more labor or invest in becoming more productive at work. At the margin, this would result in more employment for both the individual and the individual’s spouse.

Although we cannot observe the spouse’s employment directly, for each individual in our sample we observe measures of household disposable income and individual disposable income. At the household and individual levels, disposable income is calculated by our data provider by adding up all income sources and subtracting allowances for dependents (children) and adjusting for the cost of living in a particular area. From these measures, we construct the spouse’s disposable income by subtracting the individual’s disposable income from the household’s disposable income.⁴²

In columns 1, 2 and 3 of Table 7 we present the output of regression (2.1) using as outcomes the individual’s disposable income, the household total disposable income, and the spouse’s disposable income, respectively. The spouse’s disposable income can be negative due to government transfers and adjustments, which makes it impossible to use a logarithm plus one approach.⁴³ We restrict the sample of individuals to

⁴²We winsorize each of these variables at the 99th percentile.

⁴³These specifications using levels are comparable to the one we present in the Internet Appendix

those that appear as non-single as of event time 2, whose measures of household and individual disposable income are different. Although potentially underpowered, these tests show that the individual’s and household’s disposable incomes increase when their information on past defaults is removed.⁴⁴ However, column 3 shows that the spouse’s disposable income does not vary in a statistically significant manner with negative credit information, and, if anything, the point estimate is negative. This evidence suggests that access to credit, brought about through deletion of negative information, does not necessarily relax household-level credit constraints that prevent access to labor markets. This non-result, which we interpret with caution given potential issues with statistical power, is perhaps even more surprising given that the credit information of spouses is likely correlated due to joint accounts.⁴⁵

Fourth, if individuals changed their job search behavior in response to improved access to credit, then we would expect increases in applications for both credit and jobs in response to the shortened retention time. In the Internet Appendix, we show that credit inquiries do increase following the deletion of negative information. While individuals are likely to be unaware of the exact timing of their information deletion, credit card companies and other lenders actively pursue individuals they deem to be credit-worthy by monitoring credit records. However, there is no evidence that inquiries by non-financial institutions, which include employers, also increase. This evidence is more consistent with the fact that credit information affects the demand for rather than the supply of labor.

Fifth, and lastly, we exploit the information structure of the credit registries to further unpack the two potential mechanisms. In most countries, members of the credit registry—e.g., banks and other financial institutions that share information about their borrowers—have access to all the information that is collected in the credit registry, but nonmembers—e.g., employers, telephone and insurance companies and private individuals—do not.⁴⁶ This asymmetry in information exists to provide members with

Table IAV using wage as the outcome.

⁴⁴For comparability with our previous results, we present estimates using the logarithm of individual and household disposable income plus one on columns 4 and 5 of Table 7 and note strongly significant effects of the removal of past defaults on these outcomes, consistent with the evidence in the previous section.

⁴⁵Thus, it is possible that the spouse actually increases labor supply when the individual is unable to find a job due to negative credit information (Blundell et al. (2016)).

⁴⁶In the Internet Appendix, we include a figure that illustrates what information is available to members and nonmembers in Sweden.

incentives to report. Pertinently for our setting, employers cannot observe any details about individuals' arrears except whether they have an active nonpayment flag. Whereas banks are able to discriminate between a prospective borrower with ten arrears and a prospective borrower with only one arrear, employers observe identical information for a prospective employee with ten versus one arrear. If having fewer arrears is predictive of better repayment and better job performance, then both lenders and employers should want to use this information when making lending and hiring decisions. However, employers are unable to do so. This implies that in the credit market, individuals with fewer arrears should have less to gain from arrear flag deletion, while all individuals with non-payment flags should experience similar employment screening benefits, regardless of the underlying number of arrears.

In Table 8 we measure the credit and employment effects of arrear flag deletion separately for individuals with an above-median number of arrears and individuals with a below-median number of arrears. We measure the number of arrears at the time of the last nonpayment, in 2000 or 2001 depending on the defaulting cohort. In our sample, individuals with above-median arrears experience the deletion of many arrears in response to the policy change, while individuals with only one arrear experience the deletion of that singular arrear in response to the policy change. The median number of arrears in the sample is five.⁴⁷ Columns 1 and 2 of Table 8 show that the effect of the removal of the past nonpayment flag on the probability of receiving any wages is similar for individuals with many and few arrears. In column 3 we run the main regression model with full interactions with an indicator for many arrears ($Many_i$). As expected, the coefficient on the interaction of the main treatment effect with $many_i$ is small and insignificant. In contrast, columns 4 and 5 show that the effect of the removal of the nonpayment flag on credit is positive and significant only for individuals with many arrears, while column 6 shows that this difference is large and statistically significant. These patterns are, again, consistent with employer screening effects. If the employment effects were instead due strictly to improved access to credit, then we would expect symmetric patterns in labor and credit outcomes.

The findings illustrate that banks likely adjust their underwriting decisions according to the severity of an individual's past defaults. In contrast labor markets are unable to do so and are forced to pool all individuals with a non-payment flag.

⁴⁷We recognize that the number of arrears is not randomly assigned and may be correlated with other types of heterogeneity. Nonetheless, we find the results highly suggestive.

Unless the information contained in the number of arrears is relevant for banks but not for employers, then the labor cost of default imposed by credit information may be excessive for those individuals with few arrears, for example. In other words, the asymmetry of information provided to credit and non-credit market participants may lead to an inefficiency. Given that credit registries were largely designed to reduce information asymmetries in the credit market, their use in labor markets is likely only second best.

4.2 Incidence

We end our analysis by asking, for which types of individuals are the employment effects of negative credit information strongest? This question is relevant both for policy-makers and for learning about what the credit score may convey to employers.

First, we study how the effects vary for individuals with different levels of education. In Table 9 we present results for two sub-samples: individuals with 11 or fewer years of completed schooling (the median number of years of schooling), and individuals with more than 11 years of schooling. Columns 1 and 2 show that a shorter retention time strongly increases the probability of employment for individuals with little education, but it has almost no effect on individuals with many years of schooling (p -value of difference 0.035). Columns 3 and 4 show that this pattern is repeated for log wages (p -value of difference 0.095). Thus, the employment impact of negative credit information is felt more acutely by those with lower levels of education.

One possible interpretation of this heterogeneity is that past credit information is only one of many signals used by employers to infer an individual's unobserved productivity. For well-educated individuals, this information may be less relevant than other types of information (such as experience), and as such it may be down-weighted by employers. Individuals with little formal education may also have fewer ways to signal their types.⁴⁸

Second, we explore whether the effects differ by employment history, namely the preperiod (event time 2) employment status.⁴⁹ There is reason to believe that both

⁴⁸Low levels of education may also be correlated with other measures of labor market opportunities, such as industry or type of job. It might also be possible that different types of employers are more or less likely to use credit information when making hiring decisions

⁴⁹We would have liked to explore other characteristics of an individual's employment history. However, Statistics Sweden was unwilling to match other job characteristics such as type of job or industry of the employer to our credit information dataset.

the previously unemployed and previously employed may experience negative impacts. For example, negative credit information may hinder the ability of unemployed individuals to find work. This might also be the case for the many underemployed and part-time workers coded as previously employed in our sample.⁵⁰ However, individuals with long prior unemployment spells may already be severely handicapped in the labor market (e.g., Kroft et al. (2013)), even in the absence of negative credit information, and may have stopped their active job search. Thus, the additional impact of negative credit market information may be muted for this group.

In columns 1 and 2 of Table 10, we run our main specification 2.1) separately for those employed and unemployed at event time 2 (i.e., the year before arrear removal), respectively. We find similar positive effects on wage employment and on log wages for both groups (these results are statistically indistinguishable). In columns 3 and 4 we further subdivide the previously unemployed into chronically and non-chronically unemployed. We define the chronically unemployed to be those without employment at event time 2 and who additionally worked at most one year out of the three preperiod years. We find that the effects on formal employment and log wages are relatively small in magnitude (indeed, indistinguishable from zero) for the chronically unemployed, while the effects are large in magnitude for the non-chronically unemployed (p-value of difference on log wages 0.114). While underpowered, the differences in magnitudes are nonetheless striking. These results suggest that credit information may be most informative when individuals do not have other ways to signal their productivity. Long unemployment spells may provide employers with information that makes credit records superfluous.

Finally, in the Internet Appendix we show that the employment effect of shorter retention times is concentrated in geographical areas with low unemployment. Although again the test may be underpowered, one interpretation of this result is that the employment cost of default is more severe for “bad” individuals in “good times” (i.e., low unemployment areas) than for average households in high unemployment areas. Further, it is possible that the signal of productivity provided by credit information becomes more valuable when labor markets are tighter.⁵¹

⁵⁰Our data set does not allow us to differentiate part-time from full-time employment.

⁵¹It may also be the case that idiosyncratic shocks are punished more severely than aggregate shocks.

5 Conclusion

We combine a unique natural experiment in Sweden with detailed credit and labor market data to document that credit market information has economically important effects that spill over onto other domains of a borrower’s life, namely success in the labor market. We focus on a marginal population, one that is likely to experience financial distress and unemployment, for whom exclusion from the credit and labor markets is likely quite costly, and to whom policy-makers tend to pay close attention. We find robust evidence that an earlier deletion of negative credit information makes individuals more likely to be employed, and as a result, they earn higher incomes. These results highlight an understudied interlinkage between credit and labor markets. These results complement and contrast with findings by [Cohen-Cole et al. \(2016b\)](#) and [Dobbie et al. \(2016\)](#), suggesting the effects of bad credit records are likely to be heterogeneous and depend on the type of credit information being reported and on the population under study.

We also show that when labor market opportunities become scarce, individuals seek out self-employment and schooling as alternatives. These results indicate that for our sample of low income Swedes, self-employment is often an inferior alternative to the wage labor market. This finding resonates with the narrative in the entrepreneurship literature that many businesses owned by low income groups are not primed for transformative growth. The schooling response to the unemployment caused by negative credit information is also consistent with prior literature.

While credit supply is also responsive to the deletion of negative credit information, we further provide evidence that a large portion of our estimated effects is likely explained by employer screening, a practice that has increased dramatically over the past decade and that has garnered the attention of many policy-makers. Our results present some of the first causal evidence that in vulnerable populations, negative credit information can indeed impede success in the labor market. This implies that a temporary shock that causes an individual to default may have lasting and profound consequences. These results also imply that damage from credit information errors may be amplified through the labor market channel.⁵² Further, it may be difficult for households to use labor supply to smooth consumption when their credit record is

⁵²For example, see <http://www.forbes.com/sites/halahtouryalai/2013/12/17/should-your-credit-score-matter-on-job-interviews-senator-warren-says-no-aims-to-ban-employer-credit-checks/>.

poor. We also find suggestive evidence that asymmetries in the information available to non-credit entities may cause inefficiencies in the use of credit information.

Our paper estimates the employment costs of default for a particularly vulnerable population, which is an important input for modeling unsecured credit markets (e.g., [Chatterjee et al. \(2007\)](#); [Livshits et al. \(2007\)](#)) and for the policy debate. On these vulnerable populations, credit information could induce multiplier effects on unemployment (e.g. duration dependence) and potentially lead to poverty traps ([Banerjee and Duflo \(2012\)](#), [Kroft et al. \(2013\)](#)). However, we acknowledge that a full welfare analysis of employer credit screening policies requires many additional inputs and several questions remain unanswered. For example, what are the countervailing benefits from using credit information on the efficiency of matching between firms and employees? Does the employment cost of default strengthen repayment incentives and result in deeper financial markets?⁵³ These are all important questions for future work.

Some contemporaneous studies have begun to address these questions. For example, [Balance et al. \(2016\)](#) show that state-level bans on credit checks by employers increased employment but caused a deterioration of labor market outcomes of particularly vulnerable populations. [Bartik and Nelson \(2016\)](#) and [Cortes et al. \(2016\)](#) exploit the same regulation changes to find evidence of an average deterioration of labor markets, particularly for minorities, coupled with an increased demand from employers for alternative signals of applicants' productivity, such as education. These studies suggest that banning the use of credit information in hiring decisions may harm the labor market outcomes of vulnerable populations and potentially reduce welfare.

While we do not attempt such a welfare analysis, our results can provide guidance to policy-makers regarding other types of interventions that might or might not limit the negative labor market consequences from experiencing a negative shock. We find very little evidence to indicate that access to credit alone dramatically improves access to labor markets. This suggests that policies such as social transfers or subsidized government credit would be unlikely to lead to large employment benefits. Instead, policy makers might want to consider policies that either help individuals to improve

⁵³For example, individuals may want to continue to service underwater mortgages if the labor market costs are sufficiently high. Extrapolating to a different market and context, labor market costs may help to explain why strategic default was not even more common during the housing crisis ([Foote et al. \(2008\)](#)).

their credit records, such as credit counseling, or that help individuals to improve the non-credit information that they can report to prospective employers. Our results suggest that negative credit information is most detrimental for those workers with fewer alternate signals that employers can use for screening.⁵⁴

Figures

Figure 1: Frequency of removal of nonpayment flag over time

This figure displays the distribution of the removal of nonpayments over time. In the Old regime the credit registry removed all eligible arrears once a year, on December 31. Because of the bimonthly feature of our data, and because removals are inferred as differences in the stock of reported defaults, these nonpayments corresponds to the February-March bi-month (labeled February). This regime ended at the end of September 2003, when the law change came into effect and the credit registry removed arrears exactly three years to the day after the default was first reported.

Figure 2: Time line

This figure depicts the time line of the policy change that enforced a three year retention time for reporting defaults and how this policy generated variation in the retention time of the nonpayment flag. In particular, individuals whose nonpayment occurred early 2001 had a reduced retention time of past nonpayments. In contrast, individuals whose nonpayment occurred early in 2000 were reported in the credit registries until October 2003.

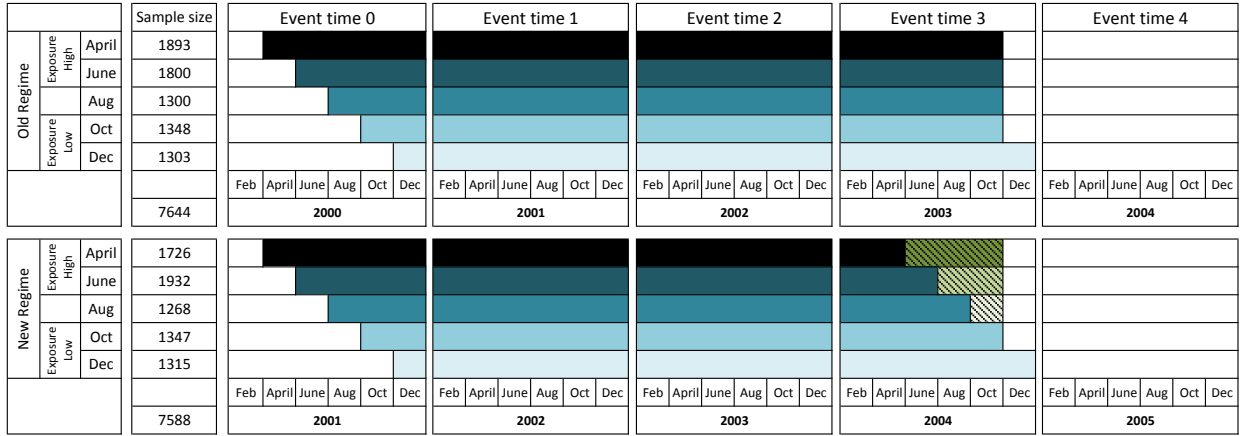

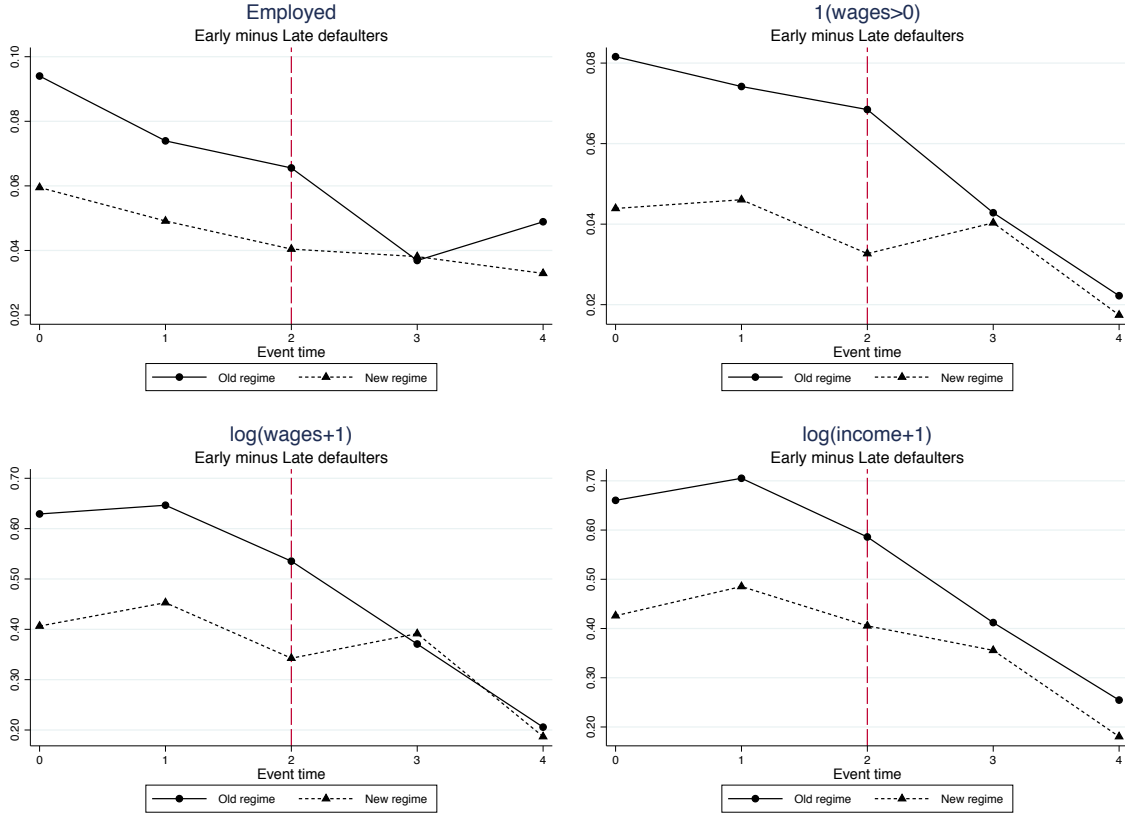

Figure 3: Pre-trends

This figure shows that there is no difference in the preperiod trends (before the policy change) of the difference between Early and Late defaulters, in the New regime and Old regime groups for our main outcomes. The top panel shows preperiod trends for *employed* and $1(\text{wages} > 0)$, which equals one if an individual received any wage income, the lower panel for $\log(\text{wages}+1)$ and $\log(\text{income}+1)$ where zeros have been replaced by 1. The solid lines represent the differences in averages of the respective outcome variables between individuals who defaulted early in the year (high exposure) and individuals who defaulted late in the year (low exposure), for individuals in the Old regime group. The dashed line represent the same difference for individuals in the New regime group.

Tables

Table 1: Average retention months

Average retention months of the nonpayment flag in the credit registry in excess of three years are shown for the New and Old regimes, who defaulted early (Feb. - May) or late (Aug. - Nov.).

	Early	Late
New regime	0	0
Old regime	6	0.5

Table 2: Outcome variables and summary statistics

Panel A defines key outcomes. Panel B presents sample stats during the three years before flag deletion, including 2000, 2001 and 2002 for the New and 2001, 2002 and 2003 for the Old regimes.

Panel A: definitions of dependent variables

<i>Employed</i>	dummy; one if the individual is employed conditional on being in labor force.
$1(Wages > 0)$	dummy; one if the individual has positive income from work.
$\log(Income + 1)$	Log of yearly post-tax income, in 100 SEK; zeros replaced by 1.
$\log(Wages + 1)$	Log of yearly pre-tax income from work, in 100 of SEK; zeros replaced by 1.
<i>Self-employed</i>	dummy; one if the individual received positive wages from entrepreneurship.
<i>Relocates</i>	dummy; equals one if individual's residence is in a different county from previous year.
<i>Years of schooling</i>	Number of years of completed education, inferred from end of year level of education.
<i>Financial inquiries</i>	number of requests for an individuals' credit report by financial institutions.
<i>Non-financial inquiries</i>	number of requests for an individuals' credit report by nonfinancial institutions.

Panel B: summary statistics

	(1)	(2)	(3)
Dependent variables	mean	std dev	median
<i>Employed</i>	0.43	0.50	
$1(Wages > 0)$	0.79	0.40	
$\log(Income + 1)$	5.62	2.91	7.03
<i>Income</i>	914	719	913
$\log(Wages + 1)$	5.57	2.97	7.04
<i>Wages</i>	1,184	1,070	1,134
<i>Self-employed</i>	0.05	0.21	
<i>Relocates</i>	0.07	0.27	
<i>Years of schooling</i>	10.70	1.76	11
<i>Financial inquiries</i>	0.52	1.05	
<i>Non-financial inquiries</i>	0.54	0.95	
<i>Age</i>	42.83	13.00	42
<i>Male</i>	0.60	0.49	
<i>Home owner</i>	0.09	0.29	
Number of individuals		15,232	

Table 3: Employment outcomes

This table shows that public information on past defaults causally reduces employment. The table shows the coefficient β from regression:

$$\begin{aligned} employed_{i,t} = & \alpha_i + \omega_t + \nu_\tau \beta early_i \times new_i \times post_{i,t} + \delta \times post_{i,t} \\ & + \gamma new_i \times post_{i,t} + \lambda early_i \times post_{i,t} + \varepsilon_{i,t}. \end{aligned}$$

Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)	(4)	(5)	(6)
Coefficient	<i>Employed</i>	<i>Employed</i>	<i>Employed</i>	1 (<i>Wages</i> > 0)	1 (<i>Wages</i> > 0)	1 (<i>Wages</i> > 0)
β	0.0280** (0.013)	0.0203* (0.012)	0.0125 (0.014)	0.0298** (0.012)	0.0299*** (0.011)	0.0295** (0.014)

Individuals	12,664	12,664	12,664	12,664	12,664	12,664

Table 4: Wages, income, and self-employment

This table shows the effects of credit information on (log)wage income, self-employment, and (log)income, using our main regression model:

$$\begin{aligned} outcome_{i,t} = & \alpha_i + \omega_t + \nu_\tau \beta early_i \times new_i \times post_{i,t} + \delta \times post_{i,t} \\ & + \gamma new_i \times post_{i,t} + \lambda early_i \times post_{i,t} + \varepsilon_{i,t}. \end{aligned}$$

Zeros are replaced by one in the log outcomes. Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)
Coefficient	log(<i>Wages</i> + 1)	<i>Self employed</i>	log(<i>Income</i> + 1)
β	0.1995*** (0.077)	-0.0137** (0.005)	0.1410* (0.075)
Post period	2 years	2 years	2 years
Obs	63,113	63,113	63,113
R^2	0.030	0.003	0.040
Individuals	12,664	12,664	12,664

Table 5: Employment outcomes with varying treatment intensity

This table shows the output of a regression that estimates the effect of longer retention time of nonpayment flags on the probability of receiving any wage income during the year. The table shows contains the coefficient β from regression:

$$1(wages > 0)_{i,t} = \omega_i + \omega_t + \omega_\tau + \beta exposuremonths_i \times new_i \times post_{i,t} + \delta \times post_{i,t} + \gamma new_i \times post_{i,t} + \sum_{t=1,3,5,7} \lambda_t 1(exposuremonths_i = t) \times post_{i,t} + \varepsilon_{i,t}.$$

There are 15,232 individuals in this sample instead of 12,664 as in previous tables because we include the June-July cohort of defaulters, which is not included in the previous tests to balance individuals with high and low exposure to the longer retention time. Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)	(4)
Coefficient	1 (<i>Wages</i> > 0)	1 (<i>Wages</i> > 0)	log(<i>Wages</i> + 1)	log(<i>Wages</i> + 1)

Individuals	15,232	15,232	15,232	15,232

Table 6: Additional results: mobility and education

This table demonstrates effects of credit market information on household mobility and education. The table contains the coefficients and standard errors for our linear triple difference in difference estimations, using *relocates*, which is a dummy that equals one if a individual's residence is in a different county and not missing from the previous event time year, and "years of schooling", which measures the number of years of education as per the individual's last completed level of education as outcomes. The number of observations is lower for "relocates" as it is defined in differences from the previous event time year, so sample period only includes event times 1 through 4 (drops event time 0). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)
Coefficient	<i>Relocates</i>	<i>Relocates</i>	<i>Years of schooling</i>

Table 7: Effects on individual's and spouse's disposable income

The table shows the regression output of our main regression model (2.1) using the individual's disposable income (Column 1), the household's disposable income (Column 2), and the spouse's disposable income, calculated as the difference between the household's and individual's disposable income (Column 3). Variables are winsorized at the 99th percentile. In columns 4 and 5 we use the logarithm of the individual's disposable income and the household's disposable income respectively, with zeros replace by one. The sample correspond to all individuals that are not single as of event time 2. The post period includes 2 years after information is deleted (event times 3 and 4). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

Table 8: Differential effects by number of arrears

This table shows differential effects of credit information on employment and credit by the number of arrears at default. The table shows the regression output of our main regression model (2.1) for different sub-samples. Columns 1 and 4 restrict the sample to individuals who had the median (five) or less arrears at the time of the last default, while columns 2 and 5 restrict the sample to those with more arrears than the median. Columns 3 and 6 use the entire sample and run the main regression model (equation 2.1) where all right hand side variables are interacted with a dummy that equals one for individuals with many arrears at the time of the last nonpayment. Outcomes include 1 ($wages > 0$), a dummy for positive wages, and *consumer*, which measures the level of consumer credit in Swedish Kronor. The post period includes 2 years after information is deleted (event times 3 and 4). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

Table 10: Heterogeneity by preperiod employment history

This table shows differential effects of credit information on employment depending on preperiod employment status. The table shows the regression output of our main regression model (2.1) for different sub-samples. In both panels A and B, column 1 restricts to a sample of individuals who are employed ($employed_{i,t}=1$) as of event time 2, the year before their information on nonpayments is removed. Column 2 restricts the sample to individuals who are unemployed as of event time 2. columns 3 and 4 split the sample of unemployed individuals. Column 3 restricts the sample to individuals who are chronically unemployed as of event time 2, defined as those individuals who have been unemployed for 2 or more years in the 3 year preperiod. Column 4 restricts to unemployed individuals who are not chronically unemployed. Panel A uses a dummy for positive wage income as outcome. Panel B uses $\log(wage+1)$, where zeros have been replaced by 1, as outcome. The post period includes 2 years after information is deleted (event times 3 and 4). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

Panel A

	(1)	(2)	(3)	(4)

Supplemental Appendix: For Online Publication Only

A Supplemental Tables and Figures

This Internet Appendix contains the following Figures and Tables:

1. Figure [IA1](#): Employment by bimonth of default
2. Figure [IA2](#): Distribution of pawn credit borrowers
3. Figure [IA3](#): Pre-trends without differencing
4. Figure [IA4](#): Retention time exposure and employment status
5. Figure [IA5](#): Credit registry information set for members and nonmembers
6. Table [IAI](#): Sweden macroeconomic indicators
7. Table [IAII](#): Summary statistics random sample Sweden
8. Table [IAIII](#): Robustness: effect of credit information on employment
9. Table [IAIV](#): Lagged outcomes
10. Table [IAV](#): Alternative specifications of wage outcome
11. Table [IAVI](#): Credit effects
12. Table [IAVII](#): Placebo test
13. Table [IAVIII](#): Effects on number of credit inquiries: financial and non-financial
14. Table [IAIX](#): Effects by labor market tightness

Figure IA1: Employment by bimonth of default

This figure depicts the average probability of receiving any wage income 2 years after defaulting in a year for individuals in our sample, by bimonth in which the default was recorded.

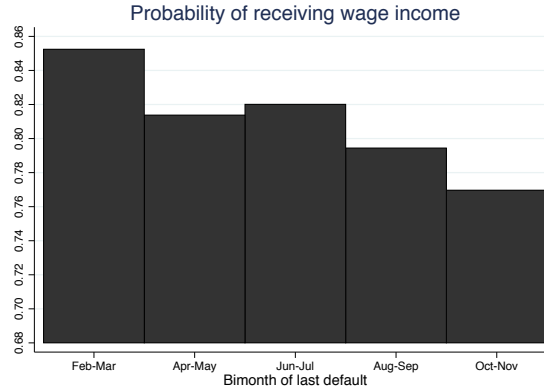

Figure IA2: Distribution of pawn credit borrowers

This figure plots the distribution of the age, after-tax income, credit score, and education of the full sample of Swedish pawn borrowers and the entire Swedish population. Figures for the Swedish population taken from a random sample provided by Statistics Sweden and the credit registry.

Figure IA3: Pre-trends without differencing

This figure shows average outcomes over event time for 2000 and 2001 cohorts of defaulters. Outcomes are: *Employed* (top panel) $1(Wages > 0)$ (middle panel), and $\log(Wages + 1)$ (bottom panel). The left plot shows raw averages for each outcome, while the right graphs plots the average of the residuals of the outcome on calendar-year fixed effects. The fraction of missing wages in 2005, which are coded as zero and reduce the average wage, is relatively high because when our data was collected a subset of Swedish firms had not yet reported to the IRS the 2005 wage income of their employees..

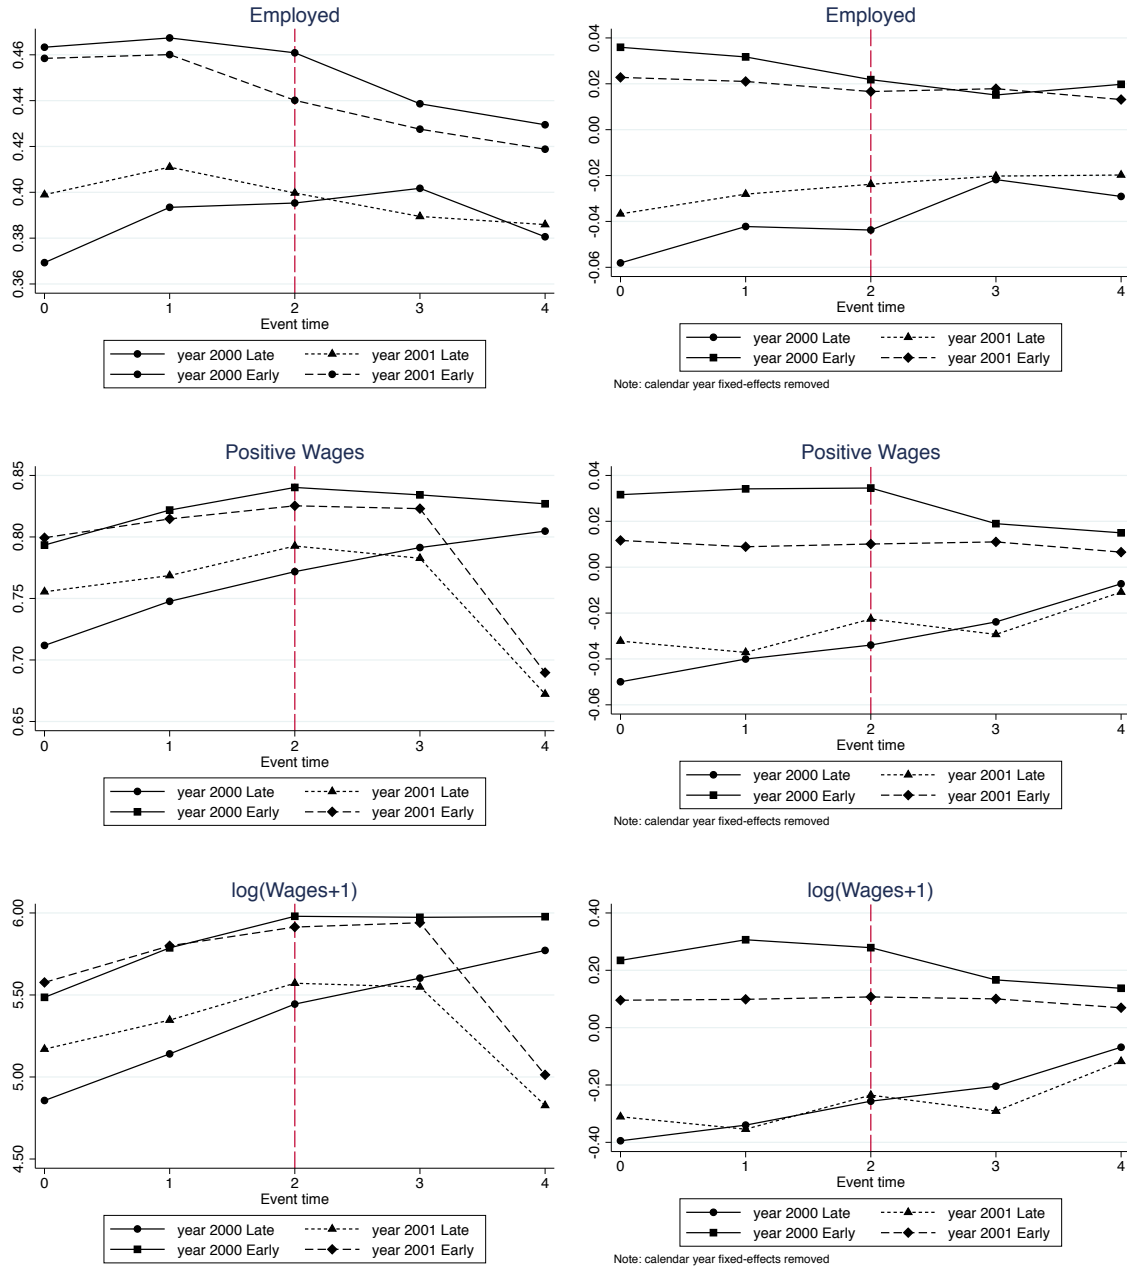

Figure IA4: Retention time exposure and employment status

The effect of credit information on labor market outcomes is monotonically stronger with exposure to the policy. The graphs show the estimated coefficients of the regression model with varying intensity of exposure, defined as the reduction in number of retention months of the New regime group relative to the Old regime group, holding fixed the calendar month of arrear receipt. The top panel uses a dummy for positive wages as an outcome, and the lower panel uses the logarithm of wage income as outcome.

Figure IA5: Credit registry information set for members and nonmembers

This figure depicts the set of variables that are available to members of the credit registry i.e. those banks and financial institutions who also contribute and share their information, and nonmembers who purchase reports from the credit registry, including employers, telephone companies, and insurance companies, among others.

	Creditbureau members	Non creditbureau members	Identity confirmation
1 Summary			
Name and address	✓	✓	✓
Social security number	✓	✓	✓
The individual data is protected (dummy variable)	✓	✓	✓
Arrear flag, bankruptcy flag (dummy variables)	✓	✓	
Income information (last tax filing)	✓	✓	
Credit relationships summarized (current total balance, limit, no.)	✓	✓	
5 arrear types (bankruptcy, debt reconstruction, prohibition to trade, collection attempt, no show at court)	✓	✓	
2 Last registered activities (12 months)	✓		
3 Personal information (age, gender, civil status etc)	✓	✓	
4 Income information from tax authorities (2 years)	✓	✓	
5 Credit engagements (per credit line, the limit, balance)	✓		
6 Real estate engagements (date, ownership share and tax values)	✓		
7 Bankruptcy application (date)	✓	✓	
8 Arrears, 99 types with date and amount, (3 year)	✓		
9 Current debt balance at Kronofogden* (amount, date)	✓		
10 Number of credit inquiries (12 months)	✓		
11 Credit score (probability to default in 12 months)	✓		

Table IAI: Sweden macroeconomic indicators

The table shows selected macroeconomic indicators for Sweden for the sample period. Source: Statistics Sweden.

	1999	2000	2001	2002	2003	2004	2005
GDP growth (annual %)	4.53	4.74	1.56	2.07	2.39	4.32	2.82
Inflation, consumer prices (annual %)	0.45	1.04	2.41	2.16	1.93	0.37	0.45
Unemployment, total (% of total labor force)	7.10	5.80	5.00	5.20	5.80	6.50	7.70

Table IAI: Summary statistics random sample Sweden

The table shows the mean and median of selected variables for a random sample of the Swedish population (columns 1 and 2) and for the same random sample conditional on having an arrear reported in the credit registry (columns 3 and 4). Summary stats obtained from credit registry data. All variable definitions in Table 2 in the main text.

	(1)	(2)	(3)	(4)
Sample	Random sample		Random sample with arrear	
Dependent variables	mean	median	mean	median
$1(Wages > 0)$	0.92		0.86	
$\log(Income + 1)$	7.04	7.52	6.43	7.23
<i>Income</i>	2,136	1,847	1,533	1,461
$\log(Wages + 1)$	6.88	7.54	6.21	7.29
<i>Wages</i>	1,989	1,881	1,498	1,460
<i>Self-employed</i>	0.05		0.07	
<i>Relocates</i>	0.06		0.08	
<i>Age</i>	43.4	43	40.9	40
<i>Male</i>	0.50		0.60	
<i>Home owner</i>	0.48		0.20	
Number of individuals	11,801		1,567	

Table IAIII: Robustness: effect of credit information on employment

The table presents robustness tests for the main regression output in Table 4 in the main text. In Panel A, we run regression (2.1) and exclude the individual fixed effects ω_i (including new_i and $early_i$ and its interaction as control variables). Standard errors are clustered at the individual level. In Panel B we return to the specification with individual fixed effects as in the main text, but cluster standard errors at the bimonth of default by 5-year preperiod age group. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

Panel A: no individual fixed effects

	(1)	(2)	(3)	(4)	(5)	(6)
Coefficient	<i>Employed</i>	<i>Employed</i>	<i>Employed</i>	1 (<i>Wages</i> > 0)	1 (<i>Wages</i> > 0)	1 (<i>Wages</i> > 0)
β	0.0294** (0.013)	0.0208* (0.012)	0.0122 (0.014)	0.0314*** (0.012)	0.0302*** (0.011)	0.0291** (0.015)
Post period	1 year	2 years	only year 2	1 year	2 years	only year 2
Obs	50,623	63,113	50,482	50,623	63,113	50,482
R^2	0.004	0.004	0.004	0.007	0.013	0.014

Individuals	12,664	12,664	12,664	12,664	12,664	12,664

Table IAIV: Lagged outcomes

The table presents the results of regression (2.1) using lagged outcomes as a specification test. Post period includes one period. The tests shows the effect of the removal of credit information on the the change in employment and credit outcomes one period *before* the year in which arrears are removed from credit records. The specifications exclude individual fixed effects. Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)	(4)	(5)
Coefficient	<i>Employed</i>	1 (<i>Wages</i> > 0)	log(<i>Wages</i> +1)	1 (<i>Consumer</i> > 0)	<i>Consumer</i>
β	0.0064 (0.013)	-0.0003 (0.011)	0.0348 (0.074)	0.0033 (0.007)	113.2918 (160.603)

Individuals	12,664	12,664	12,664	12,664	12,664

Table IAV: Alternative specifications of wage outcome

The table shows alternative specifications for our baseline wage regressions shown in Table 4. In particular, we define wages using the inverse hyperbolic sine transformation, which can be interpreted as a percentage change (Column 1), and the level of wages in 100 SEK winsorized at the 99th percentile (Column 2) and 95th percentile (Column 3). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)
Coefficient	<i>inv. hyp. sine(Wages)</i>	<i>Wages</i>	<i>Wages</i>
β	0.2321*** (0.087)	39.88* (21.93)	39.96* (20.80)
Post period	1 year	1 year	1 year
Obs	50,623	50,623	50,623
R^2	0.018	0.060	0.060
Individuals	12,664	12,664	12,664

Table IAVI: Credit effects

This table shows the baseline effect of the removal of the nonpayment flag on access to consumer credit. We focus on two outcomes: $1(\text{consumer}_{i,t})$, a dummy that equals 1 if individual i has any outstanding consumer credit at event time t , and $\text{consumer}_{i,t}$, the level of consumer credit at time t in Swedish Kronor. Details of estimation are as in Table 3. Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)
Coefficient	$1(\text{Consumer} > 0)$	Consumer
β	0.0413*** (0.008)	903.87*** (216.83)
Post period	1 year	1 year
Obs	50,515	50,515
R^2	0.009	0.005
Individuals	12,664	12,664

Table IAVII: Placebo test

This table shows the results of running our main regression test on a placebo sample. Here we define the Placebo New regime group as individuals who defaulted in 2001 and the Placebo Old regime group as individuals who defaulted in 2002. The coefficient β measures the difference in the outcome for individuals in the Placebo New regime group who defaulted early and late in the year, relative to the same difference for individuals in the Placebo Old regime group, before and after the deletion of their past nonpayment flag, which occurs on event time 3 (2004 for the Placebo New regime, 2005 for the Placebo Old regime). The post period includes only one event time year as our sample ends in 2005. Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)	(3)
Coefficient	Employed	$1(\text{Wages} > 0)$	$\log(\text{Wages} + 1)$
β	-0.0080 (0.012)	-0.0038 (0.013)	-0.0708 (0.090)
Post period	1 year	1 year	1 year
Obs	50,802	50,802	50,802
R^2	0.001	0.025	0.026
Individuals	12,713	12,713	12,713

Table IAVIII: Effects on number of credit inquiries: financial and non-financial
The table shows the regression output of our main regression model (2.1) using financial (Column 1) and non-financial inquiries (Column 2) as outcomes. The post period includes 2 years after information is deleted (event times 3 and 4). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.

	(1)	(2)
Coefficient	Non-financial inquiries	Financial inquiries

R^2	0.044	0.017
Individuals	12,664	12,664

Table IAIX: Effects by labor market tightness

This table shows differential effects of credit information on employment by the local unemployment rate by kommun. The table shows the regression output of our main regression model (2.1) for different sub-samples. Column 1 restricts the sample to communities where the unemployment rate is higher or equal than the cross sectional median of the average in in 2003-2004 (3.85%), while column 2 restricts the sample to communities where the unemployment rate is lower than the median. Column 3 corresponds to the same sample as column 2, but excluding Stockholm kommun. Outcomes are positive wage income (Panel A) and $\log(\text{wage}+1)$ (Panel B), where zeros have been replaced by 1, as defined previously. Panel C presents the same regression output using the logarithm of credit line as outcome. The post period includes 2 years after information is deleted (event times 3 and 4). Standard errors are clustered at the individual level. *, **, and *** represent 10, 5, and 1 percent significance level, respectively.
